

Section 8

Problem 1

Function $F : \{0, 1\}^* \rightarrow \{0, 1\}$ checks whether the input encodes a TM that, on every input for which it halts, outputs either a string with at most n 0s or a string with length at least n . Prove that F is uncomputable using Rice's theorem or state why Rice's theorem does not apply and show polynomial time algorithm.

Solution Rice's Theorem does not apply, because a property is secretly trivial. This is because if the output string has more than n 0s its length is also longer than n . Therefore, for every input the returned value should be 1, which we can trivially implement in polynomial time using Python.

Problem 2

Prove that if $F, G : \{0, 1\}^* \rightarrow \{0, 1\}$ are in P then their composition $F \circ G$, which is the function H s.t. $H(x) = F(G(x))$, is also in P .

Solution Lemma: First, note that the composition of two polynomial functions is polynomial: the composition of two functions f and g with degrees d_1 and d_2 respectively can have a maximum degree of $d_1 * d_2$, which is still polynomial.

For the main proof, note that if F and G are in P , then there must be NAND-RAM programs PF and PG that compute F and G respectively that run for $O(n^{k_1})$ and $O(n^{k_2})$ steps of NAND-RAM respectively, where n is the length of the input.

By the sequential composition theorem, we can construct a program PC that computes $F(G(x))$ in the following way: Start with the program PG , and compute $G(x)$. Then "paste in" the code for PF , changing the input to PF to the output $G(x)$ from PG . Note that because F is bounded by $O(n^k)$ NAND-RAM steps, it can be written as a NAND program of $O(\text{poly}(n^{k_1}))$ lines, which means the size of the output of PG can be at most $\text{poly}(n^{k_2})$. By our lemma, this upper bound on the size of the output is still polynomial, so let the size of the output of the polynomial be $O(n^c)$ for some constant c . This means that the length of the input to the code for PF is at most $O(n^c)$, so the overall runtime is $O((n^c)^k) = O(n^{ck})$, which is still polynomial.

Problem 3

Prove or disprove: F is uncomputable. Let F be the following function. On input a (string representing a) pair (M, P) where M is a Turing Machine and P is a NAND-TM program, F outputs 1 if and only if M and P are functionally equivalent, in the sense that for every $x \in \{0, 1\}^*$, either both M and P don't halt on x , or $M(x) = P(x)$.

Solution Assume for contradiction that F is computable. Reduce HALT to F .

Suppose a program T computes F . We construct a program $PHALT$ that computes $HALT$. Given a NAND-TM program P , create P' by adding line `return 0` at the end of the program.

Now we show we can compute $HALT(Q)$, by creating program $PHALT(P)$. This program:

1. creates P' as described above
2. creates M to be a TM that just returns 0
3. returns $T(M, P')$.

Suppose that P halts, then P' halts and returns 0. Since M also halts and returns 0, $T(Q, M) = 1$ and $PHALT$ returns 1, as desired.

Suppose that P does not halt, then P does not halt so $T(Q, M) = 0$. $PHALT$ returns 0, as desired.

Therefore we can compute $HALT$, which is a contradiction! Hence, F is uncomputable.

Other version of the proof uses Rice's Theorem
